Modeling

- Produce a ranking function that assigns scores to documents with regard to a given query
 - Ranking is likely the most important process of an IR system
- This process consists of two main tasks
 - The conception of a logical framework for representing documents and queries
 - Sets, vectors, probability distributions, etc.
 - The definition of a ranking function (or retrieval model) that computes a rank (e.g., a real number) for each document in response to a given query

Index Terms

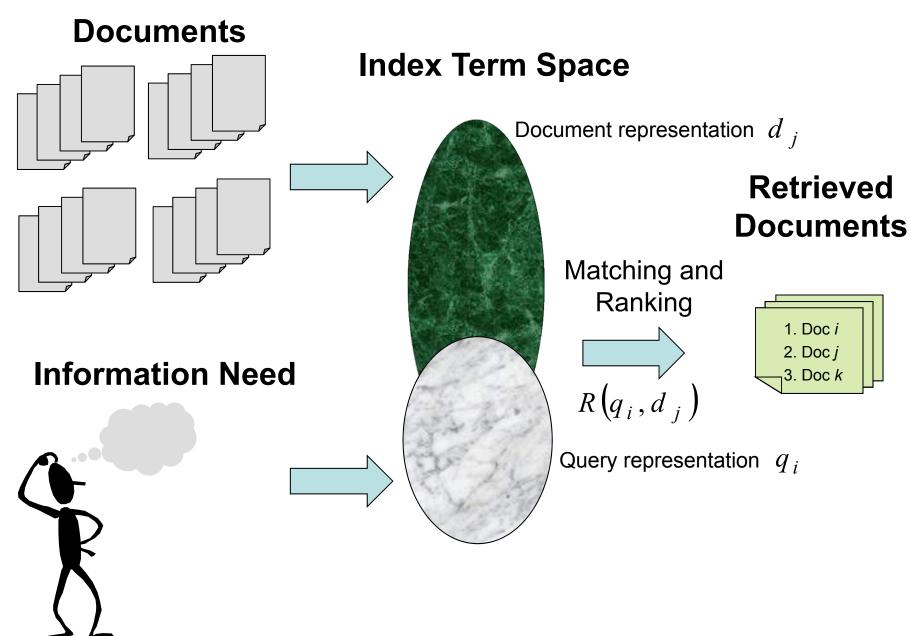

- Meanings From Two Perspectives
 - In a restricted sense (keyword-based)
 - An index term is a (predefined) keyword (usually a noun) which has some semantic meaning of its own
 - In a more general sense (word-based)
 - An index term is simply any word which appears in the text of a document in the collection
 - Full-text

Index Terms (cont.)

- The semantics (main themes) of the documents and of the user information need should be expressed through sets of index terms
 - Semantics is often lost when expressed through sets of words (e.g., possible, probable, likely)
 - Match between the documents and user queries is in the (imprecise?) space of index terms

Index Terms (cont.)

- Documents retrieved are flrequently irrelevant
 - Since most users have no training in query formation, problem is even worst
 - Not familar with the underlying IR process
 - E.g: frequent dissatisfaction of Web users
 - Issue of deciding document relevance, i.e. ranking, is critical for IR systems

Ranking Algorithms

- Also called the "information retrieval models"
- Ranking Algorithms
 - Predict which documents are relevant and which are not
 - Attempt to establish a simple ordering of the document retrieved
 - Documents at the top of the ordering are more likely to be relevant
 - The core of information retrieval systems

Ranking Algorithms (cont.)

- A ranking is based on fundamental premises regarding the notion of document relevance, such as:
 - Common sets of index terms
 - Sharing of weighted terms
 - Likelihood of relevance

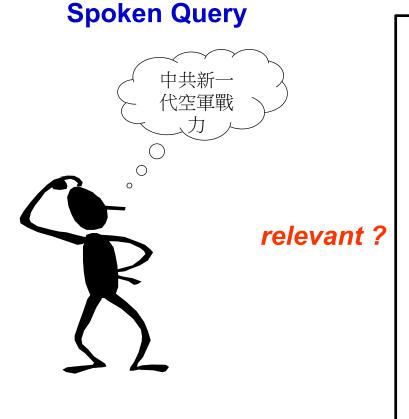

P(Q|D) or P(Q,D)?

literal-term matching

- Sharing of same aspects/concepts Concept/semantic matching
- Distinct sets of premises lead to a distinct IR models

Ranking Algorithms (cont.)

Concept Matching vs. Literal Matching

Taxonomy of Classic IR Models

- Refer to the text content
 - Unstructured
 - Boolean Model (Set Theoretic)
 - Documents and queries are represented as sets of index terms
 - Vector (Space) Model (Algebraic)
 - Documents and queries are represented as vectors in a *t*-dimensional space
 - Probabilistic Model (Probabilistic)
 - Document and query are represented based on probability theory
 - Semi-structured (Chapter 13)
 - Take into account the structure components of the text like titles, sections, subsections, paragraphs
 - Also include unstructured text

Taxonomy of Classic IR Models (cont.)

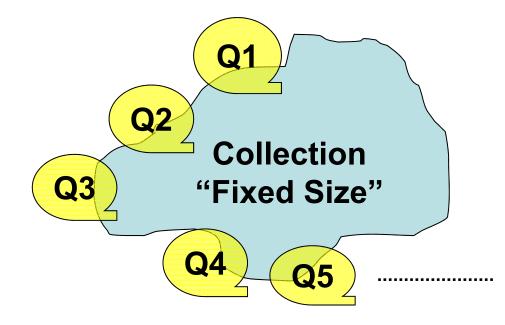

- Refer to the link structure of the Web (Chapter 11)
 - Consider the links among Web pages as an integral part of the model
- Refer to the content of multimedia objects (Chapter 14)
 - Images, video objects, audio objects

Taxonomy of Classic IR Models (cont.)

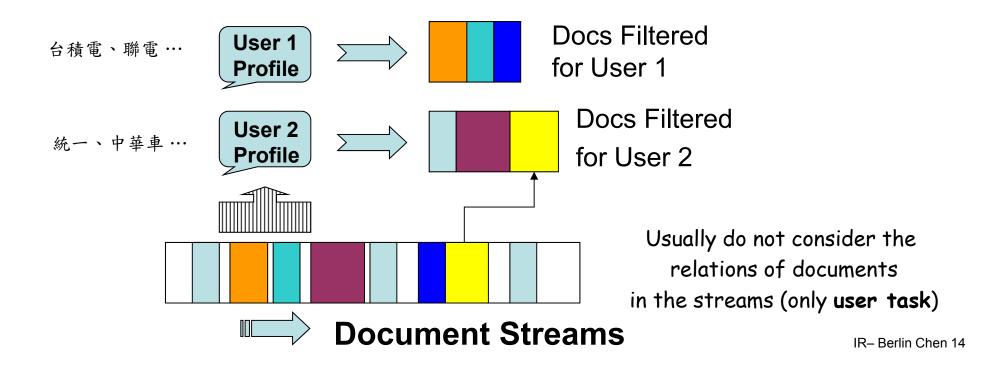

Retrieval: Ad Hoc

- Ad hoc retrieval
 - Documents remain relatively static while new queries are submitted to the system
 - The statistics for the entire document collection is obtainable
 - The most common form of user task

Retrieval: Filtering

- Filtering
 - Queries remain relatively static while new documents come into the system (and leave)
 - User profiles: Describe the users' preferences
 - E.g. news wiring services in the stock market

Filtering & Routing

- Filtering task indicates to the user which document might be interested to him
 - Determine which ones are really relevant is fully reserved to the user
 - Documents with a ranking about a given threshold is selected
 - But no ranking information of filtered documents is presented to user
- **Routing**: a variation of filtering
 - Ranking information of the filtered documents is presented to the user
 - The user can examine the Top *N* documents
- The vector model is preferred (for simplicity!)
 - For filtering/routing, the crucial step is not ranking but the construction of user profiles

Filtering: User Profile Construction

- Simplistic approach
 - Describe the profile through a set of keywords
 - The user provides the necessary keywords
 - User is not involved too much
 - Drawback: If user not familiar with the service (e.g. the vocabulary of upcoming documents)
- Elaborate approach
 - Collect information from user the about his preferences
 - Initial (primitive) profile description is adjusted by relevance feedback (from relevant/irrelevant information)
 - User intervention
 - Profile is continuously changing

A Formal Characterization of IR Models

- The quadruple /**D**, **Q**, *F*, $R(q_i, d_j)$ / definition
 - D: a set composed of logical views (or representations) for the documents in collection
 - Q: a set composed of logical views (or representations) for the user information needs, i.e., "queries"
 - F: a framework for modeling documents representations, queries, and their relationships and operations
 - $R(q_i, d_j)$: a ranking function which associates a real number with $q_i \in \mathbf{Q}$ and $d_j \in \mathbf{D}$
 - Define an ordering among the documents d_j with regard to the query q_i

A Formal Characterization of IR Models (cont.)

- Classic Boolean model
 - Set of documents
 - Standard operations on sets
- Classic vector model
 - t-dimensional vector space
 - Standard linear algebra operations on vectors
- Classic probabilistic model
 - Sets (relevant/irrelevant document sets)
 - Standard probabilistic operations
 - Mainly the Bayes' theorem

Basic Concepts

- Each document represented by a set of representative keywords or index terms
- An index term is a word or group of consecutive words in a document whose semantics is useful for remembering (summarizing) the document main themes
- Usually, index terms are nouns because nouns have meaning by themselves
 - Adjectives, adverbs, and connectives mainly work as complements
- However, search engines assume that all words are index terms (full text representation)

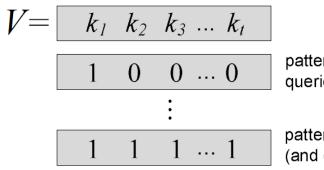

Basic Concepts (cont.)

- Let,
 - -t be the number of index terms in the document collection
 - $-k_i$ be a generic index term
- Then,
 - The **vocabulary** $V = \{k_1, \ldots, k_t\}$ is the set of all distinct index terms in the collection

$$V = k_1 \ k_2 \ k_3 \ \cdots \ k_t$$
 vocabulary of t index terms

Basic Concepts (cont.)

 Documents and queries can be represented by patterns of term co-occurrences

pattern that represents documents (and queries) with the term k_1 and no other

pattern that represents documents (and queries) with all index terms

- Each of these patterns of term co-occurrence is called a term conjunctive component
- For each document d_j (or query q) we associate a unique term conjunctive component c(d_j) (or c(q))

The Term-Document Matrix

- The occurrence of a term *k_i* in a document *d_j* establishes a relation between *k_i* and *d_j*
- A **term-document relation** between *k_i* and *d_j* can be quantified by the frequency of the term in the document
- In matrix form, this can written as

$$\begin{array}{ccc} d_1 & d_2 \\ k_1 & \left[\begin{array}{ccc} f_{1,1} & f_{1,2} \\ f_{2,1} & f_{2,2} \\ f_{3,1} & f_{3,2} \end{array} \right]$$

where each *f_{i,j}* element stands for the frequency of term *ki* in document *dj*

Basic Concepts (cont.)

- Not all terms are equally useful for representing the document contents
 - less frequent terms allow identifying a narrower set of documents
- The importance of the index terms is represented by weights associated to them
 - Let
 - k_i be an index term
 - d_i be a document
 - w_{ij} be a weight associated with (k_i, d_j)
 - \$\vec{d_j}=(w_{1,j}, w_{2,j}, ..., w_{t,j})\$: an index term vector for the document \$d_j\$
 \$g_i(\vec{d_j})=w_{i,j}\$
 - The weight w_{ij} quantifies the importance of the index term for describing the document semantic contents

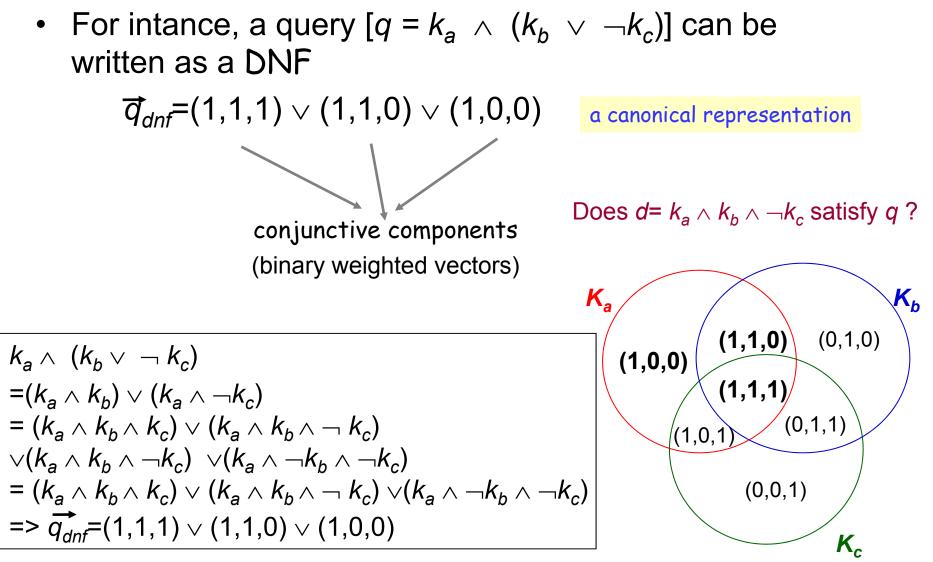

Classic IR Models - Basic Concepts (cont.)

- Correlation of index terms
 - E.g.: computer and network
 - Consideration of such correlation information does not consistently improve the final ranking result
 - Complex and slow operations
- Important Assumption/Simplification
 - Index term weights are mutually independent ! (bag-of-words modeling)
 - However, the appearance of one word often attracts the appearance of the other (e.g., "Computer" and "Network")

The Boolean Model

- Simple model based on set theory and Boolean algebra
- A query is specified as boolean expressions with and, or, not operations (connectives)
 - Precise semantics, neat formalism and simplicity
 - Terms are either present or absent, i.e., $w_{ij} \in \{0,1\}$
- A query can be expressed as a disjunctive normal form (DNF) composed of conjunctive components
 - $-\vec{q}_{dnf}$: the DNF for a query q
 - $\vec{q_{cc}}$: conjunctive components (binary weighted vectors) of $\vec{q_{dnf}}$

The Boolean Model (cont.)

IR-Berlin Chen 26

The Boolean Model (cont.)

The similarity of a document d_j to the query q (i.e., premise of relevance)

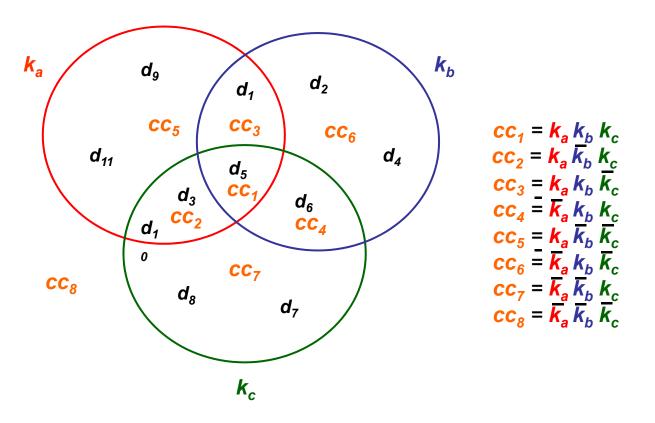

$$sim(d_{j},q) = \begin{cases} 1: \text{ if } \exists \overrightarrow{q_{cc}} \mid (\overrightarrow{q_{cc}} \in \overrightarrow{q_{dnf}} \land (\forall k_{i}, g_{i}(\overrightarrow{d_{j}}) = g_{i}(\overrightarrow{q_{cc}})) \\ 0: \text{ otherwise} \end{cases}$$

A document is represented as a conjunctive normal form

- $sim(d_j,q)=1$ means that the document d_j is relevant to the query q
- Each document d_j can be represented as a conjunctive component (vector)

Advantages of the Boolean Model

- Simple queries are easy to understand and relatively easy to implement (simplicity and neat model formulation)
- The dominant language (model) in commercial (bibliographic) systems until the WWW

Drawbacks of the Boolean Model

- Retrieval based on binary decision criteria with no notion of partial matching (no term weighting)
 - No noton of a partial match to the query condition
 - No ranking (ordering) of the documents is provided (absence of a grading scale)
 - Term freqency counts in documents are not considered
 - Much more like a data retrieval model

Drawbacks of the Boolean Model (cont.)

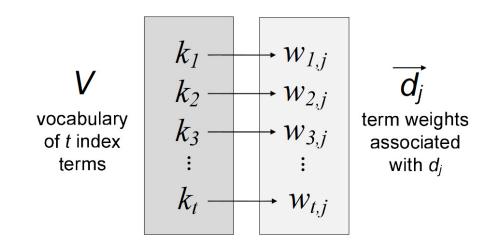

- Information need has to be translated into a Boolean expression which most users find awkward
 - The Boolean queries formulated by the users are most often too simplistic (difficult to specify what is wanted)
- As a consequence, the Boolean model frequently returns either too few or too many documents in response to a user query
- However, the Boolean model is still dominant model with commercial document database systems

Term Weighting

- The terms of a document are not equally useful for describing the document contents
- In fact, there are index terms which are simply vaguer than others
- There are (occurrence) properties of an index term which are useful for evaluating the importance of the term in a document
- For instance, a word which appears in all documents of a collection is completely useless for retrieval tasks

- To characterize term importance, we associate a weight w_{i,j} > 0 with each term k_i that occurs in the document d_j
 If k_i that does not appear in the document d_j, then w_{i,j} = 0
- The weight *w*_{*i*,*j*} quantifies the importance of the index term *k*_{*i*} for describing the contents of document *d*_{*j*}
- These weights are useful to compute a rank for each document in the collection with regard to a given query

- Let,
 - $-k_i$ be an index term and dj be a document
 - $V = \{k_1, k_2, ..., k_t\}$ be the set of all index terms
 - $w_{i,j} > 0$ be the weight associated with (k_i, d_j)
- Then we define $\vec{d_j} = (w_{1,j}, w_{2,j}, ..., w_{t,j})$ as a weighted vector that contains the weight $w_{i,j}$ of each term $k_i \in V$ in the document d_j

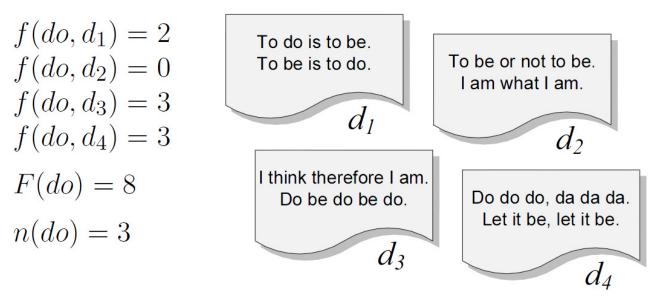

- The weights *w*_{*i,j*} can be computed using the **frequencies of occurrence** of the terms within documents
- Let *f*_{*i*,*j*} be the frequency of occurrence of index term *k*_{*i*} in the document *d*_{*j*}
- The **total frequency of occurrence** *F^{<i>i*} of term *k^{<i>i*} in the collection is defined as

$$F_i = \sum_{j=1}^N f_{i,j}$$

– where *N* is the number of documents in the collection

- The **document frequency** *n^{<i>i*} of a term *k^{<i>i*} is the number of documents in which it occurs
 - Notice that $n_i \leq F_i$
- For instance, in the document collection below, the values *f*_{*i*,*j*}, *F*_{*i*} and *n*_{*i*} associated with the term "*do*" are

Term-Term Correlation Matrix

- For classic information retrieval models, the index term weights are assumed to be mutually independent
 - This means that *wi*,*j* tells us nothing about *wi*+1,*j*
- This is clearly a simplification because occurrences of index terms in a document are not uncorrelated
- For instance, the terms computer and network tend to appear together in a document about computer networks
 - In this document, the appearance of one of these terms attracts the appearance of the other
 - Thus, they are correlated and their weights should reflect this correlation

Term-Term Correlation Matrix (cont.)

- To take into account term-term correlations, we can compute a correlation matrix
- Let $\overrightarrow{M} = [m_{ij}]$ be a term-document matrix $t \times N$ where $m_{ij} = w_{i,j}$

• The matrix $\vec{C} = \vec{M} \cdot \vec{M^t}$ is a term-term correlation matrix

 Each element c_{u,v} ∈ C expresses a correlation between terms k_u and k_v, given by

$$c_{uv} = \sum_{d_j} w_{u,j} \times w_{v,j}$$

- Higher the number of documents in which the terms k_u and k_v co-occur, stronger is this correlation

Term-Term Correlation Matrix (cont.)

• Term-term correlation matrix for a sample collection

 Further, we can take advantage of factors such as term-term distances inside documents to improve the estimates of termterm correlations (see Chapter 5)

TF-IDF Weights

- Term frequency (TF)
- Inverse document frequency (IDF)

They are foundations (building blocks) of the most popular term weighting scheme in IR, called **TF-IDF**

Term Frequency (TF) Weights

• The simplest formulation is

$$tf_{i,j} = f_{i,j}$$

The frequency of occurrence of index term *ki* im the document *dj*

• A variant of *tf* weight used in the literature is

$$tf_{i,j} = \begin{cases} 1 + \log f_{i,j} & \text{if } f_{i,j} > 0\\ 0 & \text{otherwise} \end{cases}$$

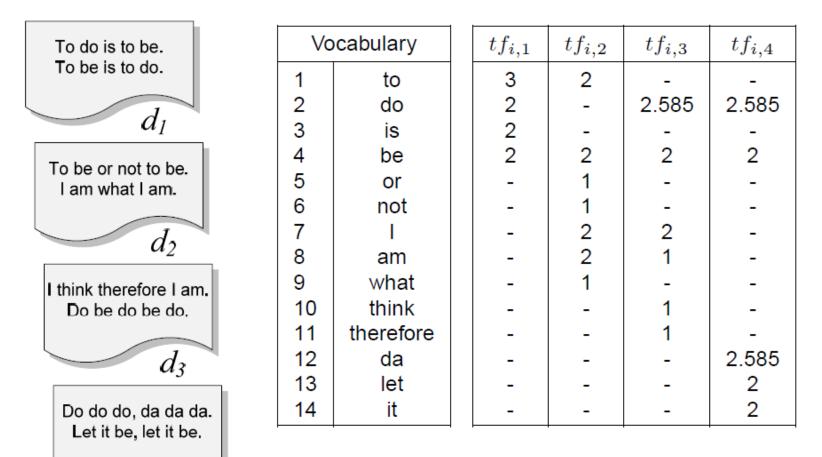

– Where the log is taken in base 2

 The log expression is a the preferred form because it makes them directly comparable to *idf* weights, as we later discuss

Term Frequency (TF) Weights: An Example

• Log *tf* weights *tf*_{*i*,*j*} for the example collection

 d_4

Inverse Document Frequency

- We call **document exhaustivity** the number of index terms assigned to a document
- The more index terms are assigned to a document, the higher is the probability of retrieval for that document
 - If too many terms are assigned to a document, it will be retrieved by queries for which it is not relevant
- **Optimal exhaustivity**: we can circumvent this problem by optimizing the number of terms per document
- Another approach is by weighting the terms differently, by exploring the notion of term specificity

Inverse Document Frequency (cont.)

- **Specificity** is a property of the term semantics
 - Term is more or less specific depending on its meaning
 - To exemplify, the term beverage is less specific than the terms tea and beer
 - We could expect that the term beverage occurs in more documents than the terms tea and beer
- Term specificity should be interpreted as a statistical rather than semantic property of the term
- Statistical term specificity: the inverse of the number of documents in which the term occurs

Inverse Document Frequency : Derivation

- Terms are distributed in a text according to **Zipf's Law**
- Thus, if we sort the vocabulary terms in decreasing order of document frequencies we have

$$n(r) \propto r^{-\alpha}$$

There is an inverse relationship between n(r) and r

- Where *n*(*r*) refers to the *r*-th largest **document frequency** and *α* is an empirical constant
- That is, the **document frequency** of term *k_i* is an exponential function of its rank

$$n(r) = Cr^{-\alpha}$$

- where C is a second empirical constant

Inverse Document Frequency : Derivation

Setting α = 1 (simple approximation for English collections) and taking logs we have

$$\log n(r) = \log C - \log r$$

- For r = 1, we have C = n(1), i.e., the value of C is the largest document frequency
 - This value (i.e., C's value) works as a normalization constant
- An alternative is to do the normalization assuming C = N, where N is the number of documents in the collection

$$\log r \approx \log N - \log n(r) = \log \frac{N}{n(r)}$$

Inverse Document Frequency : Derivation

Let ki be the term with the r-th largest document frequency, i.e., n(r) = ni. Then,

$$IDF_i = \log \frac{N}{n_i}$$
 Sparck Jones, 197

- where *id*f*i* is called the inverse document frequency of term *ki*

• IDF provides a foundation for modern term weighting schemes and is used for ranking in almost all IR systems

Inverse Document Frequency : An Example

• IDF values for example collection

To do is to be. To be is to do.		term	n_i	$idf_i = \log(N/n_i)$
	1	to	2	1
d_l	2	do	3	0.415
-	3	is	1	2
To be or not to be	4	be	4	0
I am what I am.	5	or	1	2

Do do do, da da da.	13	let	1	2
Let it be, let it be.	14	it	1	2
d_4			1	

More on Inverse Document Frequency

- In a large real collection, we expect the most selective terms to be nouns or noun groups (a noun composed of various words)
- The least selective terms are usually article, conjunctions, and prepositions which are frequently referred to as stop words
- IDF weights provide a foundation for modern term weighting schemes and are used by almost any modern IR system

TF-IDF weighting scheme

Salton and Yang, 1973

- The best known term weighting schemes use weights that combine IDF factors with term frequencies
- Let *w*_{*i*,*j*} be the term weight associated with the term *k*_{*i*} and the document *d*_{*j*}
- Then, we define

$$w_{i,j} = \begin{cases} \left(1 + \log f_{i,j}\right) \times \log \frac{N}{n_i} & \text{if } f_{i,j} > 0\\ 0 & \text{otherwise} \end{cases}$$

Which is referred to as a TF-IDF weighting scheme

TF-IDF weighting scheme: An Example

• TF-IDF weights of all terms present in our example document collection

To do is to be. To be is to do.			d_1	d_2	d_3	d_4
	1	to	3	2	-	-
d_1	2	do	0.830	-	1.073	1.073
_	3	is	4	-	-	-
To be or not to be.	4	be	-	-	-	-
I am what I am.	5	or	-	2	-	-
	6	not	-	2	-	-
d_2	7	l l	-	2	2	-
l think therefore I am. Do be do be do.	8	am	-	2	1	-
	9	what	-	2	-	-

d_3	11	therefore	-	-	2	-
	12	da	-	-	-	5.170
Do do do, da da da. Let it be, let it be.	13	let	-	-	-	4
	14	it	-	-	-	4
d_4						

Variants of TF-IDF

- Several variations of the above expression for TF-IDF weights are described in the literature
- For TF weights, five distinct variants are illustrated below

	tf weight
binary	{0,1}
raw frequency	$f_{i,j}$
log normalization	$1 + \log f_{i,j}$
double normalization 0.5	$0.5 + 0.5 \frac{f_{i,j}}{\max_i f_{i,j}}$
double normalization K	$K + (1 - K) \frac{f_{i,j}}{\max_i f_{i,j}}$

Variants of TF-IDF (Cont.)

• Five distinct variants of **IDF weights**

	idf weight
unary	1
inverse frequency	$\log \frac{N}{n_i}$
inv frequency smooth	$\log(1 + \frac{N}{n_i})$
inv frequeny max	$\log(1 + \frac{max_in_i}{n_i})$
probabilistic inv frequency	$\log \frac{N-n_i}{n_i}$

 The probabilistic inverse frequency variant arises from the classic probabilistic model, as discussed later on

Variants of TF-IDF (Cont.)

- Distinct combinations of TF variants and IDF variants yield various forms of TF-IDF weights
 - Recommended TF-IDF weighting schemes

weighting scheme	document term weight	query term weight	
1	$f_{i,j} * \log \frac{N}{n_i}$	$\left(0.5 + 0.5 \frac{f_{i,q}}{\max_i f_{i,q}}\right) * \log \frac{N}{n_i}$	Salton & Buckley
2	$1 + \log f_{i,j}$	$\log(1 + \frac{N}{n_i})$	
3	$(1 + \log f_{i,j}) * \log \frac{N}{n_i}$	$(1 + \log f_{i,q}) * \log \frac{N}{n_i}$	

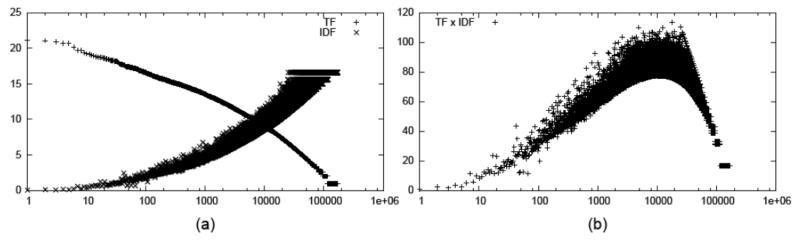

TF-IDF Properties

- Consider the TF, IDF, and TF-IDF weights for the Wall Street Journal reference collection
- To study their behavior, we would like to plot them together
- While IDF is computed over all the collection, TF is computed on a per document basis
 - Thus, we need a representation of TF based on all the collection, which is provided by the term collection frequency *Fi*
- This reasoning leads to the following TF and IDF term weight

$$TF_i = 1 + \sum_{j=1}^N f_{i,j} \qquad IDF_i = \frac{N}{n_i}$$

TF-IDF Properties (Cont.)

• Plotting TF and IDF in logarithmic scale yields

- Statistics are gathered from the Wall Street Journal collection
- The horizontal axis corresponding the rank of each term according to TF
- We observe that TF and IDF weights present power-law behaviors that balance each other
- The terms of **intermediate IDF values** display maximum TF-IDF weights and are most interesting for ranking

TF-IDF Properties (Cont.)

 Common terms (such as stopwords) and rare terms (such as foreign words or misspellings) are not of great value for ranking

Document Length Normalization

- Document sizes might vary widely
- This is a problem because longer documents are more likely to be retrieved by a given query
- To compensate for this undesired effect, we can divide the rank of each document by its length
- This procedure consistently leads to better ranking, and it is called **document length normalization**

- Methods of document length normalization depend on the representation adopted for the documents:
 - Size in bytes: consider that each document is represented simply as a stream of bytes
 - Number of words: each document is represented as a single string, and the document length is the number of words in it
 - Vector norms: documents are represented as vectors of weighted terms

- Documents represented as vectors of weighted terms
 - Each term of a collection is associated with an orthonormal unit vector $\vec{k_i}$ in a *t*-dimensional space
 - For each term k_i of a document d_j is associated the term vector
 - component $w_{i,j} \times \vec{k_i}$

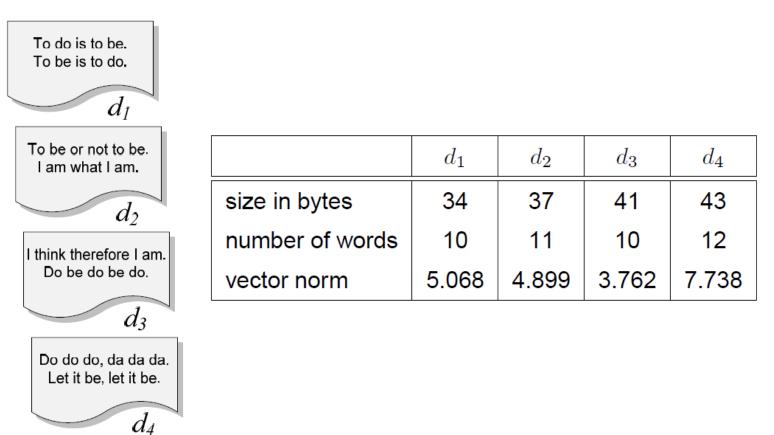

• The document representation $\vec{d_j}$ is a vector composed of all its term vector components

$$\vec{d}_{j} = (w_{1,j}, w_{2,j}, \dots, w_{t,j})$$

• The document length is given by the norm of this vector, which is computed as follows

$$\left|\vec{d}_{j}\right| = \sqrt{\sum_{i=1}^{t} w_{i,j}^{2}}$$

- Three variants of document lengths for the example
- collection

The Vector Model

SMART system Cornell U., 1968

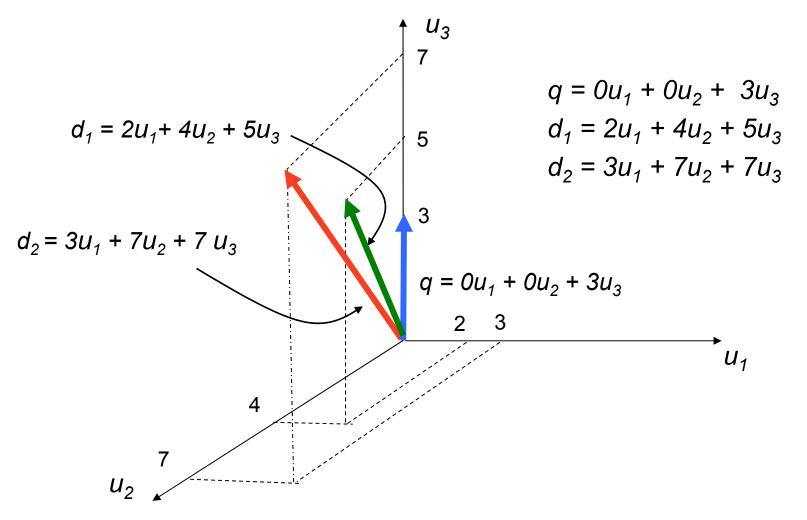

- Also called Vector Space Model (VSM)
- Some perspectives
 - Use of binary weights is too limiting
 - Non-binary weights provide consideration for partial matches
 - These term weights are used to compute a degree of similarity between a query and each document
 - Ranked set of documents provides better matching for user information need

- Definition:
 - $w_{ij} > = 0$ whenever $k_i \in d_j$
 - $w_{iq} \ge 0$ whenever $k_i \in q$

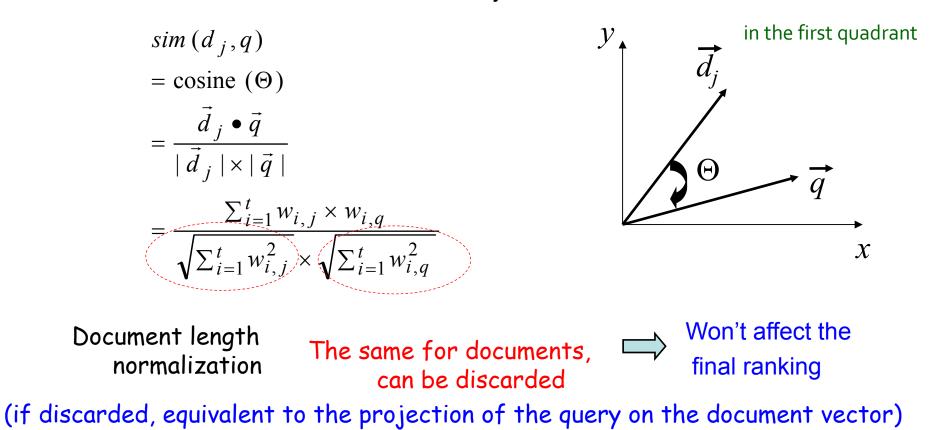

totally *t* terms in the vocabulary

- document vector $\vec{d_j} = (w_{1j}, w_{2j}, ..., w_{tj})$
- query vector $\overrightarrow{q} = (w_{1q}, w_{2q}, ..., w_{tq})$
- To each term k_i is associated a unitary (basis) vector \vec{u}_i
- The unitary vectors $\vec{u_i}$ and $\vec{u_s}$ are assumed to be **orthonormal** (i.e., index terms are assumed to occur independently within the documents)
- The *t* unitary vectors $\vec{u_i}$ form an orthonormal basis for a *t*-dimensional space
 - Queries and documents are represented as weighted vectors

- How to measure the degree of similarity
 - Distance, angle or projection?

• The similarity of a document d_i to the query q

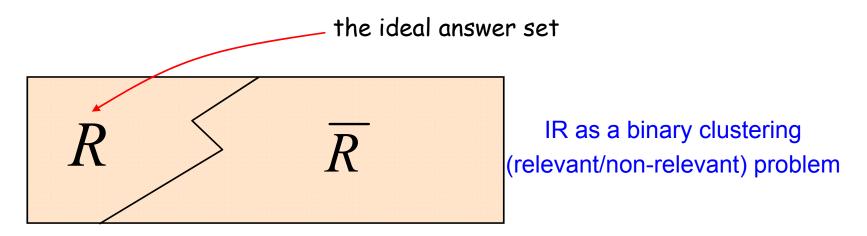

- Establish a threshold on $sim(d_j,q)$ and retrieve documents with a degree of similarity above the threshold

IR-Berlin Chen 65

- Degree of similarity \implies Relevance
 - Usually, $w_{ij} > = 0 \& w_{iq} > = 0$
 - Cosine measure ranges between 0 and 1
 - $sim(d_j,q) \approx 1 \implies highly relevant !$
 - $sim(d_j, q) \approx 0 \implies almost irrelevant !$

• The role of index terms

Document collection

- Which index terms (features) better describe the relevant class
 - Intra-cluster similarity (TF-factor)
 - Inter-cluster dissimilarity (IDF-factor)

balance between these two factors

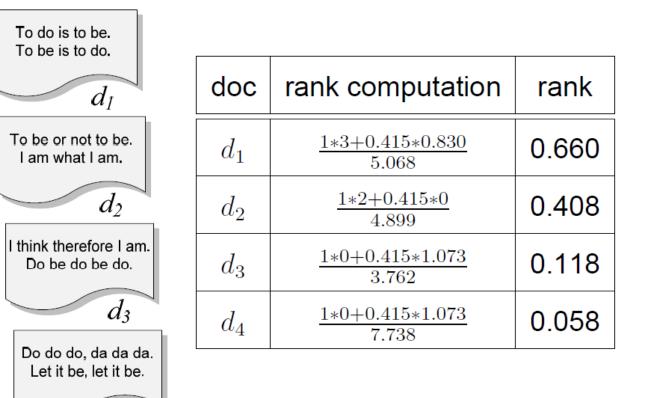

• The vector model with **TF-IDF** weights is a good ranking strategy with general collections, for example

$$w_{i,q} = \left(1 + \log f_{i,q}\right) \times \log\left(\frac{N}{n_i}\right)$$
$$w_{i,j} = \left(1 + \log f_{i,j}\right) \times \log\left(\frac{N}{n_i}\right)$$

- These equations should only be applied for values of term frequency greater than zero
- If the term frequency is zero, the respective weight is also zero
- The vector model is usually as good as the known ranking alternatives. It is also simple and fast to compute

- Document ranks computed by the Vector model for the
- query "to do" (see TF-IDF weight values in Slide 49)

 d_4

- Experimental Results on TDT Chinese collections
 - Mandarin Chinese broadcast news
 - Measured in *mean* Average Precision (*m*AP)
 - ACM TALIP (2004)

Retrieval Results for the Vector Space Model

		Word-level		Syllable-level		
Average Precision		S(N), N=1	<i>S(N)</i> , <i>N</i> =1~2	S(N), N=1	<i>S(N)</i> , <i>N</i> =1∼2	
TDT-2	TD	0.5548	0.5623	0.3412	0.5254	
(Dev.)	SD	0.5122	0.5225	0.3306	0.5077	
TDT-3	TD	0.6505	0.6531	0.3963	0.6502	
(Eval.)	SD	0.6216	0.6233	0.3708	0.6353	

$$R(q,d) = \sum_{j} w_j \cdot R_j(\vec{q}_j, \vec{d}_j),$$

types of index terms

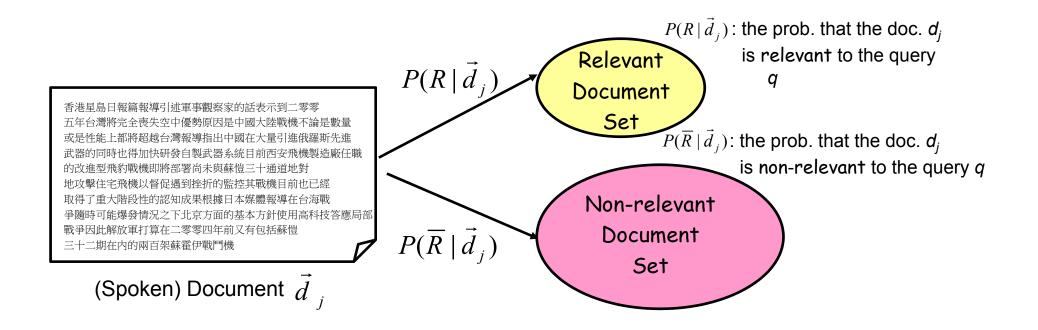

- Advantages
 - Term-weighting improves quality of the answer set
 - Partial matching allows retrieval of docs that approximate the query conditions
 - Cosine ranking formula sorts documents according to degree of similarity to the query
 - Document normalization is naturally built-in into the ranking
- Disadvantages
 - Assumes mutual independence of index terms
 - Not clear that this is bad though (??): leveraging term dependencies is challenging and might lead to poor results, if not done appropriately

The Probabilistic Model

Roberston & Sparck Jones 1976

- Known as the Binary Independence Retrieval (BIR) model
 - "Binary": all weights of index terms are binary (0 or 1)
 - "Independence": index terms are independent !
- Capture the IR problem using a probabilistic framework
 - Bayes' decision rule

- Retrieval is modeled as a classification process
 - Two classes for each query: the relevant or non-relevant documents

- Given a user query, there is an ideal answer set
 - Contain exactly the relevant documents and no others
 - The querying process as a specification of the properties of this ideal answer set (R_q)
- Problem: what are these properties?
 - Only the semantics of index terms can be used to characterize these properties
- Guess at the beginning what they could be
 - I.e., an initial guess for the preliminary probabilistis description of ideal answer set
- Improve/Refine the probabilistic description of the answer set by iterations/interations
 - Without (or with) the assistance from a human subject

• How to improve the probabilistic description of the ideal answer set ? $P(R_q \mid \vec{d}_j) > P(\overline{R}_q \mid \vec{d}_j)$

the ideal answer set K $P(\overline{R}_{q})$ $P(\overline{R}_{q} \mid \vec{d}_{j})$ $P(R_q)$ $P(R_q \mid \vec{d})$

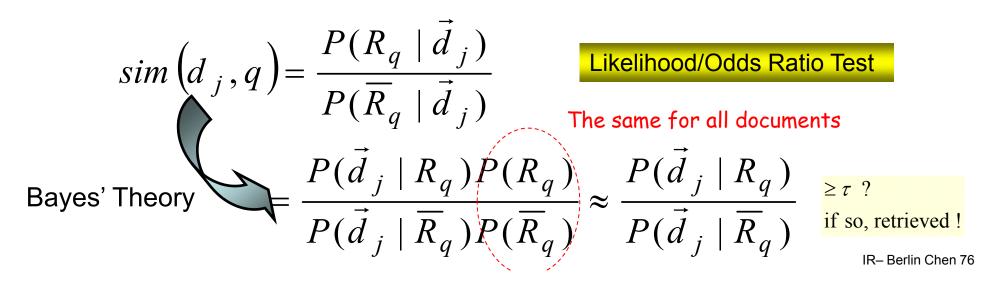

Document Collection

 Given a particular document d_j, calculate the probability of belonging to the relevant class, retrieve if greater than probability of belonging to non-relevant class

$$P(R_q \mid \vec{d}_j) > P(\overline{R}_q \mid \vec{d}_j)$$

Bayes' Decision Rule

• The similarity of a document d_i to the query q

- Explanation
 - $P(R_q)$: the prob. that a doc randomly selected form the entire collection is relevant to the query q
 - = $P(d_j | R_q)$: the prob. that the doc d_j is relevant to the query q (selected from the relevant doc set R)
- Further assume independence of index terms

$$sim \left(d_{j}, q \right) \approx \frac{P\left(\vec{d}_{j} \mid R_{q} \right)}{P\left(\vec{d}_{j} \mid \overline{R}_{q} \right)} \begin{cases} P(k_{i} \mid R_{q}): \text{ prob. that } k_{i} \text{ is present in a doc} \\ randomly selected form the set R \\ P(\overline{k_{i}} \mid R_{q}): \text{ prob. that } k_{i} \text{ is not present in a doc} \\ randomly selected form the set R \\ P(k_{i} \mid R_{q}) : P(k_{i} \mid R_{q}) \\ P(k_{i} \mid R_{q}) = 1 \end{cases}$$

$$\approx \frac{\left[\prod_{g_{i}} \left(\vec{d}_{j} \right) = 1 P\left(k_{i} \mid R_{q} \right) \right]}{\left[\prod_{g_{i}} \left(\vec{d}_{j} \right) = 1 P\left(k_{i} \mid \overline{R}_{q} \right) \right]} \left[\frac{\prod_{g_{i}} \left(\vec{d}_{j} \right) = 0 P\left(\overline{k_{i}} \mid R_{q} \right) }{\left[\prod_{g_{i}} \left(\vec{d}_{j} \right) = 0 P\left(\overline{k_{i}} \mid \overline{R}_{q} \right) \right]} \right]_{R-Berlin Chen 77}$$

- Further assume independence of index terms
 - Another representation

$$sim \left(d_{j}, q\right) \approx \frac{\prod_{i=1}^{t} \left[P\left(k_{i} \mid R_{q}\right)^{g_{i}}\left(\overline{d}_{j}\right)P\left(\overline{k_{i}} \mid R_{q}\right)^{1-g_{i}}\left(\overline{d}_{j}\right)\right]}{\prod_{i=1}^{t} \left[P\left(k_{i} \mid \overline{R_{q}}\right)^{g_{i}}\left(\overline{d}_{j}\right)P\left(\overline{k_{i}} \mid \overline{R_{q}}\right)^{1-g_{i}}\left(\overline{d}_{j}\right)\right]}$$

- Take logarithms

$$sim\left(d_{j},q\right) \approx \log \frac{\prod_{i=1}^{t} \left[P\left(k_{i} \mid R_{q}\right)^{g_{i}\left(\overline{d}_{j}\right)}P\left(\overline{k_{i}} \mid R_{q}\right)^{1-g_{i}\left(\overline{d}_{j}\right)}\right]}{\prod_{i=1}^{t} \left[P\left(k_{i} \mid \overline{R_{q}}\right)^{g_{i}\left(\overline{d}_{j}\right)}\left(P\left(\overline{k_{i}} \mid \overline{R_{q}}\right)\right)^{1-g_{i}\left(\overline{d}_{j}\right)}\right]}\right]}$$

$$The same for all documents!$$

$$P(k_{i} \mid R_{q}) + P(\overline{k_{i}} \mid \overline{R_{q}}) = 1$$

$$= \sum_{i=1}^{t} g_{i}\left(\overline{d}_{j}\right) \log \frac{P(k_{i} \mid R_{q})P(\overline{k_{i}} \mid \overline{R_{q}})}{P(k_{i} \mid \overline{R_{q}})P(\overline{k_{i}} \mid R_{q})} + \sum_{i=1}^{t} \log \frac{P(\overline{k_{i}} \mid R_{q})P(\overline{k_{i}} \mid \overline{R_{q}})}{P(\overline{k_{i}} \mid \overline{R_{q}})}$$

$$= \sum_{i=1}^{t} g_{i}\left(\overline{d}_{j}\right) \left[\log \frac{P(k_{i} \mid R_{q})}{1-P(k_{i} \mid R_{q})} + \log \frac{1-P(k_{i} \mid \overline{R_{q}})}{P(k_{i} \mid \overline{R_{q}})}\right]$$

$$R-Berlin Chen 78$$

- Further assume independence of index terms
 - Use term weighting $w_{i,q} \times w_{i,j}$ to replace $g_i(\vec{d}_j)$

$$sim(d_j, q) \approx \sum_{i=1}^t g_i(\overline{d}_j) \left[\log \frac{P(k_i \mid R_q)}{1 - P(k_i \mid R_q)} + \log \frac{1 - P(k_i \mid \overline{R}_q)}{P(k_i \mid \overline{R}_q)} \right]$$
$$\approx \sum_{i=1}^t w_{i,q} \times w_{i,j} \times \left[\log \frac{P(k_i \mid R_q)}{1 - P(k_i \mid R_q)} + \log \frac{1 - P(k_i \mid \overline{R}_q)}{P(k_i \mid \overline{R}_q)} \right]$$

Binary weights (0 or 1) are used here

 R_q is not known at the beginning \implies How to compute $P(k_i | R_q)$ and $P(k_i | \overline{R}_q)$

- Initial Assumptions
 - $P(k_i | R_q) = 0.5$ is constant for all indexing terms
 - P(k_i | R
 _q) = n_i/N :approx. by distribution of index terms among all doc in the collection, i.e. the document frequency of indexing term k_i (Suppose that |R|>>|R|, N ≈ |R|))
 (n_i: no. of doc that contain k_i. N : the total doc no.)
- Re-estimate the probability distributions
 - Use the initially retrieved and ranked Top D documents

$$P(k_i \mid R_q) = \frac{D_i}{D}$$
$$P(k_i \mid \overline{R}_q) = \frac{n_i - D_i}{N - D}$$

- Handle the problem of "zero" probabilities
 - Add constants as the adjust constant

$$P(k_i \mid R_q) = \frac{D_i + 0.5}{D+1}$$
$$P(k_i \mid \overline{R}_q) = \frac{n_i - D_i + 0.5}{N - D + 1}$$

- Or use the information of document frequency

$$P(k_i \mid R_q) = \frac{D_i + \frac{n_i}{N}}{D+1}$$
$$P(k_i \mid \overline{R}_q) = \frac{n_i - D_i + \frac{n_i}{N}}{N-D+1}$$

- Advantages
 - Documents are ranked in decreasing order of probability of relevance (optimality)
- Disadvantages
 - Need to guess initial estimates for $P(k_i | R)$
 - Estimate the characteristics of the relevant class/set R through user-identified examples of relevant docs (without true training data)
 - All weights are binary: the method does not take into account *tf* and *idf* factors
 - Independence assumption of index terms
 - The lack of document length normalization

More advanced variations of the probabilistic models, such as the BM-25 model, correct these deficiencies to yield improved retrieval.

Brief Comparisons of Classic Models

- Boolean model does not provide for partial matches and is considered to be the weakest classic model
- Salton and Buckley did a series of experiments that indicated that, in general, the vector model outperforms the probabilistic model with general collections
 - This also seems to be the dominant thought among researchers and practitioners of IR
 - The vector model, whose weighting scheme is firmly grounded on information theory, provides a simple yet effective ranking formula for general collections
